Effect of a multistage ultra-endurance triathlon on body composition: World Challenge Deca Iron Triathlon 2006

B Knechtle, O Salas Fraire, J L Andonie, G Kohler

ABSTRACT
Objective: To investigate the effect of a multistage ultra-endurance triathlon on body composition in ultra-triathletes.
Design: Descriptive field study.
Setting: The “World Challenge Deca Iron Triathlon 2006” in Monterrey, Mexico, in which every day for 10 consecutive days athletes had to perform the distance of one Ironman triathlon.
Subjects: Eight male ultra-endurance athletes (mean (SD) age 40.6 (10.7) years, weight 76.4 (8.4) kg, height 175 (4) cm and body mass index (BMI) 24.7 (2.2) kg/m²).
Interventions: None.
Main outcome measurements: Determination of body mass, protein mass, body fat, per cent body fat, mineral mass, total body water, intracellular water, extracellular water and lean body mass with a direct segmental multifrequency bioelectrical impedance method before the race and after each stage in order to show changes in body composition.
Results: A statistically significant decrease of body mass (−2.4 kg, p = 0.014), body fat (−5 kg, p = 0.0078) and per cent body fat (−6.4%, p = 0.0078) occurred at the end of the first day compared to values taken in the pre-race period. In contrast, at the same time, a statistically significant increase of protein mass (+0.7 kg, p = 0.035), mineral mass (+0.2 kg, p = 0.04), total body water (+1.8 litres, p = 0.042), intracellular water (+1.6 litres, p = 0.034) and lean body mass (+2.6 kg, p = 0.023) was shown. After the first day until the end of the challenge, body fat (−3 kg, p > 0.05) and per cent body fat (−3.9%, p > 0.05) showed a statistically significant decrease, whereas the other parameters showed no changes.
Conclusions: Athletes taking part in a multistage ultra-endurance triathlon over 10 Ironman triathlon distances in 10 consecutive days lost 3 kg of body fat; skeletal muscle mass, mineral mass and body water were unchanged.

It is well known that fat is the main energy-rich substrate for long-lasting endurance performance. Endurance exercise leads to a reduction of adipose subcutaneous tissue as demonstrated in several field studies.

Ultra-endurance races provide a good opportunity for studying the decrease of adipose subcutaneous tissue in long-lasting endurance performances. It appears that there is a different effect for performances with defined breaks (eg, during the night) and those without defined breaks. In long-lasting endurance performances with breaks, body mass may remain stable or even increase whereas skeletal muscle mass seems to be spared or may even increase. In contrast, in ultra-endurance performances for hours or even days or weeks at a time without a break, a decrease in body mass has been demonstrated, in which body fat as well as skeletal muscle mass seems to decrease.

In a study by Kimber et al, male Ironman triathletes expended in the course of one Ironman race 10 036 kcal (SD 951) and ingested 5940 kcal (SD 868), so an energy deficit of −5973 kcal (SD 1274) resulted, which must be compensated for by degradation of the body’s own energy stores. Up to now, a decrease in skeletal muscle mass as a result of ultra-endurance performance has been demonstrated only in case reports or small series. The aim of the present study was to investigate whether a larger sample of ultra-endurance triathletes would suffer only a degradation of adipose subcutaneous tissue or whether they would experience an additional loss of skeletal muscle mass following a multistage ultra-triathlon race over 10 Ironman triathlon distances in 10 consecutive days. In addition, we intended to quantify the loss of fat mass as well as the loss of skeletal muscle mass.

SUBJECTS AND METHODS
Subjects
The organiser of the World Challenge Deca Iron Triathlon 2006 contacted all participants by a separate newsletter 3 months before the race to ask them to participate in the study. All applicants gave their informed written consent. Fourteen male and 3 female caucasian ultra-triathletes started the race; 8 male athletes (mean (SD) age 40.6 (10.7) years, weight 76.4 (8.4) kg, height 175 (4) cm, body mass index (BMI) 24.7 (2.2) kg/m²) and one female athlete (age 33 years, weight 56 kg, height 170 cm, BMI 19.38 kg/m²) finished the race within the time limit. Only the 8 male caucasian athletes who finished were included in the study.

In preparation for this race, the male athletes trained on average 24 h (SD 11) per week (between 10 and 45 h) and they had previously experienced on average 18 (between 1 and 52) extreme endurance races of 24 h or longer.

The race
The World Challenge Deca Iron Triathlon 2006 was held in November 2006 as a world premiere in ultra-triathlon. The competition took place in the city of Monterrey in the Province of Nuevo León in northern Mexico, about 250 km south of the border with the USA. The race started on 6 November 2006. Seventeen ultra-endurance athletes (14 male, 3...
female) from 10 different countries and 3 continents qualified to enter the race. Every day they had to perform the distance of one Ironman triathlon of 3.8 km swimming, 180 km cycling and 42.195 km running with a time limit of 24 hours. Every morning at 09:00, the event started with swimming in the 50 m outdoor Olympic pool in the Sociedad Cuauhtemoc & Famosa Park in Monterrey, 3 km away from the cycling and running track in the Parque Niños Héroes. The pool was not heated and the water temperature was between 17°C and 21°C. Laps of 100 m were counted by personal lap counters for each athlete.

After completing the swim, the athletes changed in the transition area and, because of the enormous volume of traffic in the city, were transferred by car to the Parque Niños Héroes. A period of 50 min was allowed for transfer from the pool to the park, which was deducted from the final race time. The park was closed to traffic, completely illuminated and had a cycling track that was 95% flat, but included an inclination of 5%. The cycling consisted of 94 laps of 1.915 km each. After changing for the running course, the athletes first had to run a short lap of 705 m and then 22 laps of 1.886 km. The athletes had to climb to an altitude of 1650 m per Ironman triathlon. Drafting during cycling was strictly prohibited and controlled by the race director. Laps in the cycling and running course were counted electronically with a chip system. Athletes could be helped by their own support crew for nutrition and changes of equipment and clothes. Table 1 presents the general weather conditions and the maximum temperature each day.

During the whole race, accommodation was offered in the Sports Village of the park, about 250 m away from the race site. The athletes and their support crew had a room with bed, toilet and shower. For nutrition, the organiser offered a variety of food in a restaurant that was open 24 h.

**Measurements**

The evening before the start of the race and every evening after arriving at the finish line of one Ironman triathlon, body composition was measured with the InBody 3.0 Body composition analyser with direct segmental multifrequency bioelectrical impedance method (InBody 3.0, Biospace, Seoul, Korea). InBody 3.0 had a tetrapolar 8-point tactile electrode system and performed at each session 20 impedance measurements using four different frequencies (5 kHz, 50 kHz, 250 kHz, 500 kHz) at each of five segments (right arm, left arm, trunk, right leg, left leg). The subjects stood barefoot in an upright position on foot electrodes on the platform of the instrument, with the legs and thighs not touching and the arms not touching the torso. Four foot electrodes were used (two oval-shaped electrodes and two heel-shaped electrodes) and subjects were asked to grip the two palm-and-thumb electrodes (two thumb and two palm electrodes per athlete). They did this without shoes or excess clothing. The skin and electrodes were cleaned and dried before testing. The parameters of body mass, lean body mass, total body water, intracellular water, extracellular water, fat mass, per cent body fat, protein mass and mineral mass were directly determined.

**Statistical analysis**

The parameters were compared pairwise before the race, after the first day and after the finish. Statistical analysis was performed with the R software package (R Foundation for Statistical Computing, Vienna, Austria). The one-sample Wilcoxon signed rank test was used to check for significant changes of measured and calculated parameters before the race, after the first day and after the finish. A nonparametric method was used because the data was not ideally normally distributed. For all statistical tests, the significance level was set to 0.05. Because it was the first time a race of this kind had been held, it was necessary that this was an exploratory study of the influence of such ultra-endurance exercise. Therefore, we did not correct for multiple statistical comparisons, and our results will need to be compared with those recorded in future ultra-endurance events.

**Results**

Table 2 shows the average time taken to complete one Ironman triathlon per day.

The athletes had about 8–10 h of rest per day for recuperation. A statistically significant decrease of body mass (−2.4 kg, p = 0.014), body fat (−5 kg, p = 0.0078) and per cent body fat (−6.4%, p = 0.0078) occurred at the end of the first day compared to values taken in the pre-race period. In contrast, at the same time, a statistically significant increase of protein mass (+0.7 kg, p = 0.055), mineral mass (+0.2 kg, p = 0.04), total body water (+1.8 l, p = 0.042), intracellular water (+1.6 l, p = 0.034) and lean body mass (+2.6 kg, p = 0.023) was shown. After the first day until the finish, body fat (−5 kg, p>0.05) and per cent body fat (−3.9%, p>0.05) showed a statistically significant decrease, whereas the other parameters showed no changes (Table 3, fig 1).

**DISCUSSION**

The main finding of our investigation is that a multistage ultra-triathlon leads to a decrease in body fat, as has previously been found in ultra-endurance multisport runs. In contrast to the findings of Raschka et al’s study of a multistage ultra-endurance run, skeletal muscle mass remained stable in our investigation.

Change of fat mass during ultra-endurance performance

The ability to utilise fat as fuel is important in ultra-endurance athletes. Subcutaneous adipose tissue is the main energy source for long-lasting endurance performance. In several studies, body fat has been found to decrease in ultra-endurance performances. During a run over 1000 km within 20 days, skinfold thickness and fat mass were shown to have a tendency to decrease; only the thigh skinfold increased initially and then decreased from the 4th day onwards. Höchli et al reported a decrease of 10% body fat in runners at the Paris–Dakar FootRace over 8000 km (600 km per runner within 30 days). Cox et al demonstrated that fat-free mass was maintained with a concomitant decrease of body fat in dog drivers in a 1049-mile dogsled race. In the study of Helge et al, where four male subjects crossed the Greenland icecap on cross-country skis, body mass decreased (not statistically significant) from 79.2 kg

Because of the exploratory nature of this study, no corrections to compensate for multiple testing effects were performed.
Ultra-endurance performance leads to a decrease of body mass, mainly body fat.

In this study, we used the BIA method whereas Raschka et al used the anthropometric measurements method in their study of a multistage ultra-endurance run. BIA has been tested for its reliability and validity compared to other methods such as near-infrared interactance (NIR), skinfold measurements and dual energy X-ray absorptiometry (DEXA). When BIA is compared with the skinfold method and near-infrared interactance, it appears to be more accurate in a wide range of different individuals.

Both the skinfold and BIA methods seem to be sufficiently accurate on the narrow sample of subjects on which they were developed and both methods show a fairly good correlation with DEXA as a reference method. BIA seems to be a valid field method for athletic status but in two studies, the authors concluded that the body composition parameters may be better estimated by the skinfold method. One problem is that fluid changes often are interpreted as changes in fat mass where the skinfold method provides the lowest body fat mass when DEXA, BIA and the skinfold method are compared.

CONCLUSIONS
Athletes taking part in a multistage ultra-endurance triathlon over 10 Ironman triathlon distances in 10 consecutive days lost 5 kg of body fat; skeletal muscle mass, mineral mass and body water were unchanged. For future studies of multistage races, we recommend determining skeletal muscle mass and fat mass using two different methods such as BIA and the skinfold method, and measuring haematological and urine parameters in order to quantify fluid metabolism.

Commentary

The effect of an ultratriathlon (10 Ironman triathlon distances in 10 days) on eight athletes (mean age 40.6 years, mean BMI 24.7 kg/m²) taking part in the World Challenge Deca Iron Triathlon 2006 (Monterrey, Mexico) was examined using direct multifrequency bioelectrical impedance analysis. The athletes lost 3 kg of body fat, whereas muscle mass, mineral mass and body water did not change. The loss of 1.75 kg body mass is equal to the loss of 1.75 kg body mass in an ultra-endurance run over 1000 km within 20 days as described earlier in 1992. In this race the loss of body mass was measured anthropometrically.

Christoph Josef Raschka, Institut für Sportwissenschaften der Universität Frankfurt, Frankfurt, Germany; craschka@gmx.de
